1. Introduction

Oxidation in machining is one of the mechanisms – alongside with abrasion, adhesion, and diffusion – which govern tool deterioration [1].

Investigation of the oxygen impact on the machining process requires the use of oxygen-free environment, such as in a vacuum or inert gas chamber [1–9]. Majority of studies address the issues of machining mechanics: cutting forces [2, 3], tool–chip contact length [4, 5], friction [4, 6], build-up edge formation [2], and surface quality [2]. It was shown that the impact of the oxygen-free environment is defined by the tool-workpiece material pair. Machining of iron [2, 5] and copper [3] in vacuum demonstrate an increase of forces and contact length, while machining of aluminium [6] results in decreased or invariable force and contact parameters for carbon steel, HSS and coated tooling.

The impact on tool wear, however, was given less attention. It was shown that the reduction of O2 content results in the decrease of notch wear for cemented carbide tools [7, 10]. Similar impact of the oxygen-free environment was found on the tool rake cratering in turning copper [9] and milling stainless steel [8].

In this study, oxidation wear mechanism in high speed machining with cemented carbide, cermet, pCBN tooling and different workpiece materials was investigated.

2. Experimental work

The developed controlled environment chamber represents a steel box with gas curtain tubing in the upper part (Fig. 1a).

Another gas supply circuit represents 3 secondary nozzles attached above and on the sides of a toolholder. Gas is also introduced into the cutting zone through 3 primary nozzles of PJDN3225F15ETL (Seco Tools) high pressure jet holder (Fig. 1a and b). The curtain and secondary nozzles are connected to one gas flow regulator, while the primary nozzles to another regulator. Frontal box opening was covered with a safety glass for visual observation of the machining process. The lower part of the chamber has an opening for chip evacuation.

ARCAL Prime gas supplied by Air Liquide with the purity of argon 99.998% and content of O2 ≤ 5 ppm was used in the tests. Initial machining tests with a flow rate of 35 l/min and gas pressure of 1.8 bar through each set of nozzles has shown insufficient protection of the tool rake and the flank, similarly to Ref. [7]. Increase of the flow per nozzle set to 100 l/min at 3.2 bar prevented oxidation on the tool rake, however oxide deposit on the flank remained in the direct vicinity of the wear land. Only one nozzle supplies argon directly to the flank while five nozzles and the curtain protect the rake. Further increase to 200 l/min at 4.7 bar ensured approx. 250 μm band of oxide free region on the flank (Fig. 1d). Therefore a total of 400 l/min, or one complete exchange of atmosphere in the controlled environment chamber every 0.15 s, was maintained during the machining tests in Ar. After disengagement the gas flow was kept for another 180 s to exclude tool oxidation during cooling.

Machining on air was done under identical conditions, but using filtered compressed air, in order to assert similar gas circulation and cooling. It was shown [5] that the oxygen partial pressure of ≤1 mbar or ≤0.1% was sufficient for oxidation prevention in machining ferrous alloys, and therefore current setup is referred to as oxygen-free environment throughout the paper.

Machining was done at two cutting speeds, while depth of cut and feed were selected to ensure proper chip breaking and
evacuation (Table 1). Wear of four tool material grades, including cemented carbide, cermet and pCBN, was investigated in machining alloyed steel, hardened cold work tool steel, and aged Alloy 718.

Optical microscopy and 3D reconstruction was performed on a Alicona InfiniteFocus. Scanning electron microscopy (SEM) was performed on a Tescan Mira3 equipped with field emission gun and Oxford EDX detector. Focus ion beam (FIB) lamella preparation was performed on a FEI Nova NanoLab 600 dual beam FIB/SEM. Standard in-situ lift-out procedure was employed where the lamellae were thinned to electron transparency (approx. 100 nm) using 10 kV Ga+ ions. Transmission electron microscopy (TEM) was performed on a JEOL 3000F equipped with field emission gun and Oxford EDX detector.

Uncoated P10 grade of cemented carbide was selected because it has been shown to have highest resistance to oxidation wear among the steel cutting grades [10]. Uncoated cermet with Ni-Co binder was also selected for its high resistance to oxidation [11]. CBN170 (Seco Tools) is a SiC whisker reinforced grade with 65 vol.% content of CBN and multi-modal grain size distribution specifically designed for machining superalloys. CBN100 (Seco Tools) is a signature grade with 50 vol.% content of CBN and TiC binder for finishing hard machining. All inserts were of ISO DN4150608 type geometry. Cemented carbide and cermet have commercial chip-breakers. CBN100 has a chamfer with $b_\gamma = 0.1$ mm land and $\gamma_\gamma = 20^\circ$ angle. CBN170 has a flat rake.

### 3. Results and discussion

Fig. 2 shows the evolution of the cutting forces against flank wear (VB) for all machining cases. It can be seen that the influence of oxygen-free environment depends on the tool-workpiece material pair, as also reported in Ref. [3]. Strongest impact was found in machining with cemented carbide where argon environment resulted in an increase of $F_\gamma$ force by $\approx 15\%$ and by $\approx 25\%$ for feed $F_\delta$ and passive $F_o$ forces. In machining with cermet only the cutting force component $F_\gamma$ was increased by $\approx 10\%$ (Fig. 2b). In machining Alloy 718 force data are inconclusive, because an additional mechanism of notching and premature edge failure (Fig. 7) dominates forces more than the environment.

Williams and Tabor [5] attributes the increase of forces in the oxygen-free environment to disappearance of slip zone and expansion of stick zone over the entire tool–chip contact, also observed in this study (Fig. 8c). This is also accompanied by larger contact length [2,3,5]. Application of commercial chip-breakers in our study creates restriction to a contact zone, thus limiting force increase only to stick zone effect.
mechanism outweighed (Figs. 3d and 4a) the other temperature-driven mechanisms such as diffusion and abrasion. Hard machining at lower cutting speed resulted in identical rake cratering, yet the crater wear was significantly intensified when machining on air at \( v_c = 200 \text{ m/min} \) (Fig. 4a). This indicates that the oxidation mechanism was thermodynamically activated [13] at such high cutting speed (process temperature). Crater wear of \( K_T \geq 30 \mu \text{m} \) lead to complete tool fracture.

Using optical microscopy, Trent and Wright [11] identified oxidized and non-oxidized regions on worn tool, where the oxide films were always found a distance away from the tool–chip–workpiece contact zone. The composition was interpreted from variations in colour and contrast. They assumed that adsorption of oxygen by the newly formed surfaces, also as found in Ref. [6], depleted the atmosphere around the edge, thus naturally creating oxygen-free pocket preventing near-edge oxidation. Also in our study, optical microscopy of worn cermet and carbide tools showed similar features. However, SEM BSE microscopy depicted a dark near-edge band which, combined with EDX mapping, demonstrate the formation of oxides over the entire clearance face (Fig. 5). EDX line scan along the clearance (Fig. 5b and c) shows: (i) higher O content, simultaneously with depletion of W, indicative of the formation of WO\(_3\) directly next to the cutting edge, and (ii) higher than background O levels and normal W further down are implying formation of TiO\(_2\) film. Identical phenomena were found on the rake and in all other machining cases with carbide and cermet tooling. These findings prove, though oxygen adsorption does occur [6] it is insufficient to form an oxygen-free pocket that prevent oxidation.

Despite the observed intensification of flank wear when machining in oxygen-free environment (Fig. 3), its impact on the notch wear formation was found to be positive. Machining on air with carbide and cermet tooling was accompanied by notching on the major (Fig. 6a) and minor cutting edge. Yet, notching was completely blocked in argon environment (Fig. 6b). These findings are attributed to an easier abrasion of the above demonstrated WO\(_3\) and TiO\(_2\) oxides by the burrs [1].

However, a contrary influence on notching occurred in machining Alloy 718 with CBN170, where machining in argon resulted in significantly higher notch formation (Fig. 7). Adhesion and pluck-out of the tool material by the chips and burrs in machining Alloy 718 [14] was intensified in the absence of oxide film formation. Additionally, notching in argon expanded laterally.

leading to a gradual cutting edge deterioration and collapse (Fig. 7b).

Fig. 8b demonstrates the formation of a pronounced oxide layer formed outside the crater of CBN170 tool after machining on air. Fig. 8c illustrates the absence of such oxides, thus confirming oxygen-free environment when machining in argon. When machining on air, two contact zones are distinguished in the contact area (Fig. 8b), alongside with considerable workpiece material adhesion, as verified by EDX Ni element mapping. Additionally, presence of Al and O in the crater suggests the formation of Al\(_2\)O\(_3\). Machining in argon (Fig. 8c) results in a single contact zone and suppression of material adhesion. Doyle et al. [4] demonstrated presence of stick (zone 1) and slip (zone 2) regions on the rake (Fig. 8a). Zone 2, in their study, was characterized by gross transfer of chip material onto the rake, as also seen in Ref. [15] and in our study. They attribute this mechanism to the formation of oxide films in this region and higher friction coefficient in the presence of oxides. Thus it can be concluded that oxygen-free environment promotes stick region (zone 1).

Fig. 9 shows scanning (STEM) dark field (HAADF) images from thin cross sections of CBN170 and CBN010 tool rake surfaces prepared by FIB after machining on air. In both cases, preferential removal of cBN phase is observed, as seen by the position of interface line between the adhered metal and tool material. The mechanism is believed to be diffusional, where elemental boron and nitrogen are dissolved in the chips. The metal–cBN interface moves faster than the binder, which is then abraded [16], and eventually the entire cBN grain is consumed and replaced by a metal. However, this phenomenon is more pronounced when hard machining Caldie tool steel (Fig. 9b), as compared to machining Alloy 718 (Fig. 9a).

SEM and associated EDX data did not reveal the presence of oxide films directly on the tool–chip or tool–workpiece interfaces, which is expected due to limitations of thin film detection for this technique. Therefore, FIB prepared cross section lamellae were investigated with TEM. As can be seen in Fig. 10a, a layer of iron
oxide is located atop a grain of TiC, yet no TiO₂ was found. The adhered film of Fe is believed to have oxidised upon cooling after tool disengagement. Oxide was not found in the sample of CBN10 when hard machining on air (Fig. 10b) either. Despite the absence of oxides when inspecting the samples with SEM and TEM, the mechanism of oxidation wear cannot be ruled out. The expected

4. Conclusions

Oxidation wear mechanism in high speed machining with cemented carbide, cermet and pcBN tooling was investigated. The results indicate that the impact of oxygen-free environment on the cutting forces varies for different tool-workpiece pairs. Flank wear was found to be more intensive when machining in argon, except for the case of hard machining with pcBN. In this case, cratering was found to be more intensive in oxidative atmosphere. However, the oxidation mechanism was activated only at high cutting speed. In contrast, cratering was reduced in machining Alloy 718 due to oxidation of workpiece material and formation of a deposit of Al₂O₃ on the tool. Concurrently, reaction of the workpiece and cBN resulted in TiN deposit, both of which acted as diffusion barrier.
